# ABSTRACT

Carbon dioxide, heavy hydrocarbon, hydrogen sulfide, water vapor and toluene are the common impurities found in raw natural gas that can bring detrimental effects on the performance of membrane. The heavy hydrocarbon contamination can cause the loss of flux and membrane performance and thus it is imperative for pretreatment of the natural gas feed stream to remove the contaminants. This project is to study the effect of heavy hydrocarbon on the polyimide membrane performance in separating gas CO<sub>2</sub> from natural gas feed stream at designed operating parameters, i.e. feed pressure, temperature and  $CO_2$  concentration in feed. Liquid Pentane ( $C_5H_{12}$ ) is used as a basis to simulate the presence of heavy hydrocarbon in the experiments. Gas permeation experiments have been conducted in laboratory to study the effect of pentane on Polyimide membrane performance. It is proven that permeance of CO<sub>2</sub> and CH<sub>4</sub> will decrease with an increase in operating pressure at feed side in both dry and wet condition. The CO<sub>2</sub>/CH<sub>4</sub> selectivity increases with an increase in feed pressure. Higher operating temperatures increased CO<sub>2</sub> and CH<sub>4</sub> permeance but decreased CO<sub>2</sub>/CH<sub>4</sub> selectivity of polyimide membrane. An increase in CO<sub>2</sub> concentration in feed composition increases the losses of hydrocarbon but reduced CO2, CH4 permeance and CO2/CH4 selectivity. The decrease of membrane permeance and selectivity with an increase in CO<sub>2</sub> concentration in the feed composition is due to the plasticization and coupling effect. The pentane presence in the feed gas caused swelling or plasticization of polyimide membrane and lead to the reduction in membrane selectivity. It was concluded that the presence of pentane as heavy hydrocarbon in natural gas stream contributed to the loss of membrane selectivity and caused the separation performance of the membrane system become less efficient.

# ACKNOWLEDGEMENTS

In the preface of this report, I would like to take the opportunity to acknowledge all the parties that assisted me either directly or indirectly particularly to UTP for providing laboratory equipment, facilities and manpower for me during my final year project and make this as a successful and memorable project.

First and foremost, I would like to express my sincere gratitude to **Dr. Lau Kok Keong** for being my supervisor of final year project. As a senior lecturer in the university, Dr. Lau always shares his knowledge, guidance and motivation to me throughout this project. With the help from Dr. Lau, I managed to overcome several problems encountered and finished the project on time.

I am sincerely grateful to Post Graduate student, Ms. Nor Wahyu Binti Jusoh and technician from Block N, Mr. Samad for their assistance and guidance throughout the FYP lab sessions. Special thanks to the technicians from Chemical Engineering Department for providing the equipment and chemicals needed for the experiments.

Finally, I would like to thank my parents and friends for their endless support and motivation throughout my studies in UTP. To those who assisted me during my FYP, I hope our connections remain and may their work life be filled with blessing and satisfaction in the future.

## **CHAPTER 1**

# **INTRODUCTION**

# 1.1 RESEARCH BACKGROUND

Natural gas is a fuel that burns cleaner and more environmentally attractive than other traditional fossil fuels as it emits lower quantities of greenhouse gases during combustion. Raw natural gas contains typically 75% to 90% of methane from the total composition and significant amounts of ethane, propane, butane, and 1% to 3% of other higher hydrocarbons (Baker & Lokhandwala, 2008). In addition, the raw natural gas contains undesirable impurities, such as water, carbon dioxide, nitrogen, and hydrogen sulfide. The composition of Carbon dioxide, CO<sub>2</sub> found in the natural gas streams can reach as high as 80% from the total composition. Carbon dioxide, a type of acid gases, is highly corrosive when mixed with water and it will rapidly destroy pipelines and equipment (Dortmundt & Doshi, 1999). In addition, carbon dioxide reduces the heating value of natural gas and freezes at a relatively high temperature, forming blocks of dry ice that can clog equipment lines and damage pumps (Bernardo, Drioli, & Golemme, 2009). Therefore, it is very important to control the composition of gas delivered to the pipeline grids although the composition of raw gas varies widely (Baker & Lokhandwala, 2008).

Carbon dioxide removal from natural gas, also known as natural gas sweetening, is mandatory to meet pipeline specifications limit the CO<sub>2</sub> concentration to 2 mole percent, the H<sub>2</sub>S concentration to 4 ppm and water vapour concentration to 0.1 g/m<sup>3</sup> (Lee et al., 1995). There are many types of acid gas removal technologies are available for natural gas sweetening in the market. Each process has its own advantages and

disadvantages. Acid gas removal technologies include absorption processes, such as the Benfield<sup>TM</sup> process (hot potassium carbonate solutions) and Amine Guard-FS<sup>TM</sup> process (formulated solvents); cryogenic processes; adsorption processes, such as pressure swing adsorption (PSA), thermal swing adsorption (TSA) and membranes processes (Dortmundt & Doshi, 1999). Conventional natural gas processing has included absorption type processes, using either chemical or physical type solvents (amines or glycol-based systems) to remove CO<sub>2</sub>, H<sub>2</sub>S and H<sub>2</sub>O (Lee, et al., 1995). Cryogenic distillation is essentially a fractional distillation of gaseous mixture by exploiting the difference of relative volatilities of CO<sub>2</sub> and CH<sub>4</sub> (Rahman, Aizan, & Ismail, 2005). Adsorption processes operate as an equilibrium or kinetic process depending on the desire product and adsorbent (Y. Yampolskii, 2012).

Membrane gas separation is a pressure-driven process that consists of thin barriers that allow selective permeation of certain gases. A synthetic membrane is a thin barrier between two phases through which differential transport can occur under a variety of driving forces including pressure, concentration and electrical potential across the membranes (Koros, Ma, & Shimidzu, 1996). Membrane gas separation does not require a phase change and presents significant advantages for remote application such as offshore gas-processing platform (Bernardo, et al., 2009). With the flexible design, the compactness and the efficiency of membrane units, membrane gas separation by polymer membranes is a proven technology that is more attractive compared to conventional gas separation methods like cryogenic distillation, absorption or adsorption. (Staudt-Bickel & J Koros, 1999). Membrane plants are generally preferred when processing small gas flows and able to treat high-concentration gas streams much more efficiently than low concentration gas streams. Membrane plant is less complex than amine (Baker & Lokhandwala, 2008). Membranes are predominately based on polymeric materials (Wong & Bioletti, 2002). In an industrial process, the purification of natural gas can be accomplished with membrane systems where it requires a membrane with high selectivity for carbon dioxide to methane (White, Blinka, Kloczewski, & Wang, 1995). Polyimides have been identified as materials with high selectivity for CO<sub>2</sub>/CH<sub>4</sub> (White, et al., 1995).

# **1.2 PROBLEM STATEMENT**

One of the most important emerging applications of membrane technology is the usage of membrane systems in the natural gas sweetening processes. Membrane technology for separating gases helps in reducing the environmental impact and costs of industrial processes. Natural gas contains a wide variety of contaminants that can reduce the membrane effectiveness and force premature replacement of the elements. The membrane performance can be easily affected by the presence of heavy hydrocarbon and impurities such as CO<sub>2</sub>. Membrane may undergo plasticization or swelling effects when exposed to heavy hydrocarbons or CO<sub>2</sub> with high partial pressure, even in low concentration. Polymeric asymmetric membrane performance can be dramatically reduced by the presence of heavy and condensable hydrocarbons in natural gas streams (Vu, Koros, & Miller, 2003a). Therefore, it is very important to perform pretreatment of the natural gas in feed stream to remove the contaminants such as CO<sub>2</sub>, liquids, heavy hydrocarbons and particulate material. There are two situations where liquid hydrocarbons can form within the membrane surface and cause loss of flux and selectivity of membrane. The first one is Joule-Thomson effect results in the gas cools down and the formation of heavy hydrocarbon within the membrane. The second case is when the CO<sub>2</sub> permeates and the gas becomes heavier in hydrocarbons and its dew point therefore increases through the membrane (Paul, Lloyd, & Eldridge, 2004).

Generally, polymeric membranes cannot withstand high temperatures and aggressive chemical environments. The presence of heavy hydrocarbon in feed gas streams can bring detrimental effects to the membrane, particularly in polyimide flat sheet membrane, when applied in petrochemical plants, refineries, off-shore gas processing platform, and natural gas treatment plants. As a result, it is important to evaluate separation performance of membrane material under adverse conditions. The study of the effect of heavy hydrocarbon in natural gas sweetening processes is important to evaluate the performance of membrane systems. The present research works only demonstrated limited studies on this potential problem for the polyimide membrane material. Due to the complexity of heavy hydrocarbon and other impurities in natural gas, the impact of these components on the membrane system has remained

poorly understood until today. Also, previous research works showed that it is difficult to characterize the effects of heavy hydrocarbon and impurities experimentally. It is often a challenge to truly simulate the real working environment of a membrane in the laboratory due to the difficulties in identifying the environmental conditions and constraints. Generally, the membrane device in the field has to be robust enough to withstand deterioration due to the wet conditions found with natural gas streams.

In addition, the conventional membrane separation research works for the natural gas sweetening are mainly focused on low feed  $CO_2$  composition and low feed pressure. There are scarce works on the performance of membrane materials in high concentration of carbon dioxide and high pressure operating conditions. It is important to study the maximum limit pressure and feed  $CO_2$  composition for the membrane elements to achieve a cheaper and more effective membrane system. Experimental works in laboratory that simulates field conditions assist in the study of limitations to the polymer and membrane in natural gas sweetening process. Therefore, it is imperative to conduct researches on adverse conditions, particularly on high  $CO_2$  composition in feed stream and high feed pressure, and to study the polymeric membrane performance.

There is a significant interest in research of the effects of heavy hydrocarbons on the membrane performance since these components contribute to loss in permeability and selectivity. Also, it is important to evaluate separation performance of polyimide membrane material in natural gas sweetening under adverse conditions for membrane development in the future.

# 1.3 **OBJECTIVE AND SCOPE OF STUDY**

#### 1.3.1 Objective

The main objective of this work is to study the effect of heavy hydrocarbon on the polyimide membrane performance in removing gas  $CO_2$  from natural gas feed stream at designed operating parameters, i.e. feed pressure, operating temperature and  $CO_2$  concentration in feed. Liquid Pentane,  $C_5H_{12}$ , is used as a basis to simulate the presence of heavy hydrocarbon in the experiments.

#### **1.3.2** Scope of Works

In order to achieve the objective stated above, the following scope of works has to be conducted:

- To perform preliminary literature research on the commercial membrane, particularly on polyimide membrane.
- To conduct parametric studies for polyimide membrane separation under different operating parameters and conditions in experimental lab for two consecutive semesters. Feed pressure, operating temperature and feed composition (%CO<sub>2</sub> concentration) are the important parameters to be studied in the project.
- To compare the performance of the polyimide membrane in separating CO<sub>2</sub> from natural gas in two different conditions, namely Dry Condition (Without the presence of Pentane as hydrocarbon impurities) and Wet Conditions (with Pentane).
- To discuss and analyze the possible effect of heavy hydrocarbon on the performance of polyimide membrane.

# CHAPTER 2

# LITERATURE REVIEW

# 2.1 MEMBRANE TECHNOLOGY

Membranes which are thin semipermeable barriers between feed and permeate gas streams have been used to selectively separate some compounds from others (Dortmundt & Doshi, 1999). The widest application for gas separation membranes is the removal of acidic gases,  $CO_2$  and  $H_2S$  from raw natural gas. For natural gas sweetening,  $CO_2$  is collected in the low pressure permeate stream whereas  $CH_4$  is enriched in the high pressure retentate stream. The advantages of membranes are cost effectiveness, low capital investment, ease of operation, low energy consumption, space efficiency, good weight and suitable to be used in remote locations, particularly offshore gas processing platform (Dortmundt & Doshi, 1999).

Figure 2.1: Membrane unit for natural gas sweetening. Adapted from (Schmeling, Konietzny, Sieffert, Rölling, & Staudt, 2010)

## 2.2 MEMBRANE PERMEATION

In petrochemical processing polymer membranes are used commercially to separate air, to remove carbon dioxide from natural gas and to remove hydrogen from mixtures with nitrogen or hydrocarbons. The fundamental parameters characterizing membrane separation performance are the permeability coefficient,  $P_A$ , and the selectivity, $\propto_{A/B}$ . In one-dimensional diffusion through a flat membrane, the local flux, N of a penetrant can be described by Fick's law as shown in the following equation:

$$N = -D \left[ \frac{\partial C}{\partial x} \right] \tag{1}$$

where the diffusion coefficient, D, may be a function of local concentration, C (Fick, 1995).

The permeability coefficient, P is generally defined as the flux, N normalized by pressure and membrane thickness.

$$P = \frac{N}{(p_2 - p_1)/l} \tag{2}$$

Thereby,  $p_2$  and  $p_1$  are upstream and downstream pressures of the penetrants and l is the membrane thickness. Permeation is a solution-diffusion process. Permeability is the rate at which any compound permeates through a membrane; it depends upon a thermodynamic factor and kinetic factor (Bernardo, et al., 2009). Therefore, the permeability coefficient can be expressed as a product of an average diffusion coefficient, D and a solubility coefficient, S (Koros, Flemming, Jordan, Kim, & Hoehn, 1988).

$$\mathbf{P} = \mathbf{S} \cdot \mathbf{D} \tag{3}$$

The solubility coefficient is determined by the condensability of the penetrants, by the polymer-penetrant interactions and by the amount of excess volume existing in the glassy polymer. The diffusion coefficient, D, is a measure of mobility of the penetrants between the upstream and downstream conditions of the membrane (Staudt-Bickel & J Koros, 1999). The permselectivity of a membrane for gas separations is characterized by a separation factor,  $\propto_{A/B}$  defined in terms of the downstream (y) and upstream (x) mole fractions of two components A and B is given in the following equation:

$$\mathbf{x}_{A/B} = \left(\frac{\mathbf{y}_A}{\mathbf{y}_B}\right) \left(\frac{\mathbf{x}_B}{\mathbf{x}_A}\right) \tag{4}$$

In cases where the downstream pressure is negligible, the separation factor  $\propto_{A/B}$  is equal to the ratio of permeabilities of the two gases A and B under mixed gas feed conditions as show in the following equation:

$$\propto_{A/B}^{*} = \frac{P_A}{P_B} \tag{5}$$

The ideal separation factor,  $\propto_{A/B}^*$  is a measure of the intrinsic permselectivity of a membrane material for mixtures of A and B.

The ideal separation factor can be split into two parts:

$$\propto_{A/B}^{*} = \left(\frac{D_{A}}{D_{B}}\right) \cdot \left(\frac{S_{A}}{S_{B}}\right) \tag{6}$$

where  $\frac{D_A}{D_B}$  is the diffusivity selectivity and  $\frac{S_A}{S_B}$  is the solubility selectivity.

Membranes used for  $CO_2$  removal operate on the principle of solution-diffusion through a nonporous membrane. Gas separation membrane processes are mostly based on the sorption of the permeant into the membrane, permeation by diffusion through the membrane, desorption at the low pressure side of the membrane (Bernardo, et al., 2009).

Polymeric membranes are further classified as glassy or rubbery dependent on the value of their glass transition temperature relative to ambient (Scholes, Stevens, & Kentish). Glassy polymers (mainly cellulose acetate and polyimides) dominate industrial carbon dioxide separation applications such as the separation of carbon dioxide from methane, carbon monoxide, nitrogen or other hydrocarbons (Morisato & Pinnau, 1996). Glassy polymeric membranes are based on diffusivity selectivity (Scholes, et al.). The gas  $CO_2$  first dissolves into the membrane and then diffuses through it. The membrane separates based on how well different compounds dissolve

into the membrane and then diffuse through it. Fast gases are gases that permeate quickly such as carbon dioxide, hydrogen, helium, hydrogen sulfide and water vapor. Slow gases are the gases that permeate less quickly, for example, carbon monoxide, nitrogen, methane, ethane and other hydrocarbons. The membranes allow selective removal of fast gases from slow gases (Dortmundt & Doshi, 1999).

Figure 2.2: Glassy polymers separate gases principally by size. Adapted from Baker & Lokhandwala (2008).

Rubbery polymeric membranes are the focus due to their ability to separate based on gas condensability. Heavy hydrocarbons are able to permeate at a greater flux than methane (Scholes, et al.). Rubbery polymers have attracted greater interest for the separation of carbon dioxide from hydrogen due to higher flux rates and high selectivity.

Figure 2.3: Rubbery polymers separate gases principally by condensability. Adapted from Baker & Lokhandwala (2008).

Rubbery and glassy polymers can also separate carbon dioxide and hydrogen sulfide from natural gas. However, in practice,  $CO_2$  is best separated by glassy polymer membranes that maximizing size selectivity whereas  $H_2S$  is best separated by rubbery polymer membranes that maximizing sorption selectivity (Baker & Lokhandwala, 2008).

Despite of the large number of polymeric materials investigated and developed for gas separation applications, the number of polymers used in commercial system is still limited. The main rubbery and glassy polymers employed for gas separation membranes are listed in **Table 2.1** (Bernardo, et al., 2009).

**Table 2.1:** Most Important Glassy and Rubbery Polymers Used in Industrial MembraneGas Separation. Adapted from Bernardo, et al. (2009).

### 2.3 POLYIMIDES

Polyimides are rigid, high-melting point, and thermally stable polymers obtained by polycondensation reactions of dianhydrides with diamines (Bernardo, et al., 2009). Polyimides are a class of polymer that display high permeability for carbon dioxide and good selectivity again methane. They are easy to prepare as asymmetric membranes while demonstrating good thermal and chemical stability and they are viewed as an alternative to cellulose acetate (Tanaka, Taguchi, Hao, Kita, & Okamoto, 1996). Polyimides exhibit an exceptional combination of thermal stability (>500 °C), mechanical toughness and chemical resistance (Rahman, et al., 2005). In addition to high selectivities, polyimide possess high glass transition temperatures, (T<sub>g</sub> > 200°C). A polyimide that is available in the market is Matrimid<sup>®</sup> 5218. Its permeation properties, combined with its process ability make it an attractive candidate for gas separation application. Furthermore, its mechanical strength and high glass transition temperature, better suit it for more rigorous working environments than other non-cellulosics such as polysulfone (Al-Juaied & Koros, 2006).

### 2.4 MEMBRANE STRUCTURE

For industrial applications, polymeric membranes can be classified broadly into three classes based on flux density and selectivity: porous, non-porous and asymmetric (Pandey & Chauhan, 2001). According to Pandey & Chauhan (2001), a porous membrane is a rigid, highly voided structure with randomly distributed inter-connected pores whereas non-porous or dense membranes provide high selectivity or separation of gases from their mixtures but the rate of transport of the gases are usually slow.

Asymmetric membranes consist of two structurally distinct layers, one of which is an extremely thin nonporous layer mounted on a much thicker and highly porous layer of the same material as shown in **Figure 2.4**. The nonporous layer is highly selective and thin whereas the porous layer provides mechanical support and allows the free flow of compounds that permeate through the nonporous layer. The drawback for asymmetric membranes are they are costly to make out of exotic, highly customized polymers, which often can be produced only in small amounts (Dortmundt & Doshi, 1999).

Figure 2.4: Asymmetric membrane structure. Adapted from Dortmundt & Doshi (1999).

### 2.5 MEMBRANE ELEMENTS

There are three main types of membranes commercially available for CO<sub>2</sub> removal: cellulose acetate, polyimides and perfluoropolymers (Sridhar, Smitha, & Aminabhavi, 2007). In addition to their gas permeation properties, these polymers are all easy to process through to membrane modules, are mechanically strong and have thermal and chemical resistance to ensure long term viability (Sridhar, et al., 2007). The first membrane systems to separate carbon dioxide from natural gas were introduced by Grace Membrane Systems, Separex, and Cynara. These companies used anisotropic cellulose acetate membrane that was produced using the Loeb-Sourirajan technique (Kohl & Nielsen, 1997).

Cellulose acetate membranes are still widely used. In the last 10 years, they have begun to be challenged by newer membranes, such as the polyimide membranes (made by Medal a division of Air Liquide) (Simmons, Kulkarni, & Ekiner, 2006) and perfluoropolymer membranes (made by ABB/MTR) (Y. P. Yampolskii, Pinnau, & Freeman, 2006).

Figure 2.5: Cellulose Acetate

Figure 2.6: Polyimides

Figure 2.7: Perfluoropolymers

Good membrane module designs consist of the following attributes: high packing density, cost-effective manufacturing, low pressure drops on feed and permeate sides, minimal concentration polarization and have good flow pattern and flow distribution (Rahman, et al., 2005). There are six type of membrane module available and used today on a large industrial scale such as plate and frame module, spiral wound module, capillary membrane module, hollow fiber module and tubular membrane module (Paul, et al., 2004). Gas separation membranes are manufactured in one of two forms: flat sheet or hollow fiber (Dortmundt & Doshi, 1999).

Membranes for gas separation are usually formed as hollow fibers arranged in the tube-and-shell configuration and the flat sheets are typically packaged as spiralwound modules (Wong & Bioletti, 2002). Two flat sheets of membrane with a permeate spacer in between are glued along three of their sides to form an envelope that is open at one end in the spiral wound module arrangement (Dortmundt & Doshi, 1999).

Figure 2.8: Spiral wound membrane element. Adapted from Paul, et al. (2004).

Most of the gas separation membranes today are formed into hollow-fiber modules, with perhaps fewer than 20% being formed into spiral-wound modules (Baker, 2002). In hollow-fiber elements, very fine hollow fibers are wrapped around a central tube in a highly dense pattern. Feed gas flows over and between the fibers and some components permeate into them. The permeated gas travels within the fibers until it reaches the permeate pot and exits the element through a permeate pipe (Dortmundt & Doshi, 1999).

Figure 2.9: Hollow-fiber membrane element. Adapted from Dortmundt & Doshi (1999).

## 2.6 EFFECT OF IMPURITIES ON THE MEMBRANES PERFORMANCE

The presence of heavy hydrocarbons in the natural gas feed streams can lead to a great impact to the membrane systems. The membrane systems may loss in performance or failure due to the present of very heavy hydrocarbons in the natural gas streams. Loss of flux and/or selectivity due to heavy hydrocarbon exposure can be detrimental to membrane performance in the field. Therefore, it is very important to carefully consider the required pretreatment requirements for membrane systems. Previous work on membrane formation has led to successful formation and modeling of reliable membrane structures for  $CO_2$  removal from natural gas feeds (Clausi & Koros, 2000).

According to Staudt-Bickel and J. Koros (1999), the gaseous feed stream can be composed of over 50% CO<sub>2</sub> at elevated temperature and up to a feed pressure of 60 atm in extreme cases. The CO<sub>2</sub> present in the feed stream can result in the swelling and plasticization of most membrane materials under extreme operation conditions. In enhanced oil recovery applications (EOR), fractured wells and in landfill gas recovery processes are some of the interest areas of CO<sub>2</sub>/CH<sub>4</sub> separation with the use of polymeric membrane. The membranes are exposed to high CO<sub>2</sub> concentrations in the feed stream in some of these applications (Staudt-Bickel & J Koros, 1999).

There have been limited studies on evaluating the performance of polymeric membrane and hollow fibers due to the effects of heavy hydrocarbon vapor impurities in natural gas feed streams. Most of the research works have shown that the presence of heavy hydrocarbon vapor impurities contributed to detrimental effect on the polymeric membranes performance (Vu, et al., 2003a). Cellulose acetate membranes tend to show relatively low intrinsic  $CO_2/CH_4$  selectivity, with no loss in flux or  $CO_2/CH_4$  selectivity for contaminants such as benzene, toluene and xylene in natural gas streams (Schell et al., 1989). Polyimides have been identified as materials with high selectivities for  $CO_2/CH_4$  (Tanaka, et al., 1996). For glassy polymeric membranes, particularly polyimide, with intrinsically high selectivity, one study cites harsh performance decline in the range of 50% reduction in  $CO_2/CH_4$  selectivity accompanied with plasticization due to saturated concentrations of toluene or hexane in mixed gas feeds of  $CO_2/CH_4$ 

(White, et al., 1995). Similar research has been done with 100 ppm and 300 ppm of toluene and n-heptane in 10%  $CO_2/90\%$  CH<sub>4</sub> gas feeds showed similar selectivity losses (about 30-50%) for asymmetric polyimide hollow fibers membrane module (Djoekita, 2000). In addition to selectivity losses, reductions in flux (30 – 60%) were also observed and were attributed to competition effects and possible compaction of the transition layer in the asymmetric hollow fiber structure (Djoekita, 2000). High selectivity polyimide membrane materials may be susceptible to heavy hydrocarbon exposure because of their greater reliance on diffusivity selectivity (White, et al., 1995). Therefore, disruption of polymer chain mobility possibly caused by condensable penetrants can play a more detrimental role in diffusivity-selectivity polymers. As a result, heavy and condensable hydrocarbons have been suspected of causing membrane performance declines in the fields. Mixed matrix membranes, a new class of hybrid membrane materials, have attractive  $CO_2/CH_4$  separation properties comprising highly selective carbon molecular sieve (CMS) particles dispersed within glassy polymer matrices (Vu, Koros, & Miller, 2003b)

For glassy polymeric membranes, the effect of heavy hydrocarbons or impurities in pure carbon molecular sieve (CMS) membranes is an important concern. Toluene and n-heptane were separately used as representative aromatic and paraffinic impurities, respectively, in 10% CO<sub>2</sub>/90% CH<sub>4</sub> gas feeds streams containing up to 300 ppm of these impurities at shell-side feed pressures of up to 900 psia and temperatures of 35 and 50 °C (Vu, et al., 2003a). In this work, Vu et al. show that the CMS membranes maintained CO<sub>2</sub>/CH<sub>4</sub> selectivity with only 7-20% reduction in CO<sub>2</sub> permeance during exposure to gas feeds containing these impurities, in comparison to natural gas feeds without these impurities. The results demonstrated that the impurity penetrants are only effective in entering and blocking non-selective micropores and are not able to enter the smaller and selective ultra-micropores.

### 2.7 MEMBRANE POTENTIAL DETERIORATION FACTORS

The difference between the membrane permeability and selectivity under the influence of heavy hydrocarbon can be caused by the following possible non-ideal effects: (i) competition (ii) plasticization (iii) compaction (iv) conditioning and (v) concentration polarization. (Al-Juaied & Koros, 2006; Paul, et al., 2004).

#### (i) Competition Effect

The presence of a penetrant that inhibits the transport of the other components contributed to this effect. According to Chern et al, the competition effect should be most apparent for highly condensable feed components, like toluene as suggested by the dual mode sorption theory. If this effect is present and depresses the  $CO_2/CH_4$  selectivity, the selectivity should return to the original value upon removal of the preferentially sorbing penetrant. During exposure to such "C" components, sorption and transport (permeation) pathways are precluded to A and B, thereby reducing their ternary gas permeation in comparison to binary feeds.

Figure 2.10: Depiction of competition effect caused by a third component, C, in a membrane system. Adapted from Al-Juaied & Koros (2006).

### (ii) Plasticization

This effect happens when the presence of a given component in a polymer matrix causes the diffusion, and hence permeation of other components to increase compared to the case without that component present due to a swelling-induced facilitation of a local segmental motion.  $CO_2$  or toluene, a strongly sorbing component, can cause plasticization even in the absence of other penetrants (Al-Juaied & Koros, 2006). The most important plasticizing component in natural gas is carbon dioxide. Membrane materials absorb 30-50 cm<sup>3</sup>(STP) of  $CO_2/(cm^3 \text{ polymer})$  at the high pressure of natural gas operations, and this is equivalent to 5-10 wt% of  $CO_2$  in the polymer and thus, the membrane materials become plasticized (Baker & Lokhandwala, 2008). Plasticization is apparent as non-constant, upwardly inflecting permeability or permeance as a function of  $CO_2$  or toluene feed pressure (Jordan, Fleming, & Koros, 1990).

# (iii) Compaction Effect

Plasticized glassy structures exposed to high trans membrane pressure can have reduced moduli and undergo significant rearrangements of the super-molecular morphology leading to a denser microstructure (Djoekita, 2000). The compaction can lead to subtle densification of the finely porous transition region between the more or less dense skin region and the highly porous support layer in an asymmetric hollow-fiber membrane. This results in added mass transfer resistance to the membrane. Such a change tends to reduce permeance and selectivity of all components. Hence, the effect of compaction will be a decrease in the flux and decrease in the selectivity (Paul, et al., 2004).

## (iv) Swelling Induced Conditioning Effect

The exposure to a highly sorbing gas like  $CO_2$  at high pressures will cause an increase in sorption and dilation levels as compared to levels in an as-received or unconditioned sample (Jordan, et al., 1990). This phenomena has been explained in part by attributing the increase in subsequent sorption and dilation levels to an increased number of subtle packing disruptions in the non-equilibrium polymer matrix, which makes it energetically easier for penetrant molecules to be sorbed and to diffuse (Al-Juaied & Koros, 2006). The swelling induced conditioning effect (SICE) is more pronounced if the secondary penetrant is introduced while the sample is still exposed to the conditioning agent. Upon exposing a glassy sample to a highly sorbing penetrant at a pre-determined pressure and then evacuating completely before exposure to the second penetrant, less dramatic effects are apparent. Toluene, an aromatic substance, is suspected to act as potent SICE agents due to its high condensability (Paul, et al., 2004).

#### v) Concentration Polarization

The feed mixture components permeate the membrane at different rate in membrane separation processes and cause a gradual build-up in the concentration of nonpermeating or slowly permeating components in the feed. A layer is formed near the surface of the membrane, whereby the solution immediately adjacent to the membrane surface becomes depleted in the permeating solute on the feed side of the membrane, and its concentration is lower than that in the bulk fluid. The concentration of the nonpermeating component increases at the membrane surface. Concentration polarization is the polarization component that is caused by the concentration changes in the environment adjacent to the membrane surface, it serves to reduce the permeating components' concentration difference across the membrane and thus reduce flux and selectivity. Concentration polarization can be minimized by increasing turbulent mixing at membrane surface to reduce the film thickness (Wind, Paul, & Koros, 2004).

# **CHAPTER 3**

# **METHODOLOGY**

# 3.1 RESEARCH METHODOLOGY

In this project, **polyimide membrane** is used to study the effect of heavy hydrocarbon on the membrane performance in removing gas carbon dioxide from natural gas under different operating parameters. The performance of a membrane is characterized by the selectivity and permeance for asymmetric membrane. The permeance, P/t, is the pressure normalized flux and is the preferred productivity measure for asymmetric membranes where the actual thickness of the selective skin layer is not clearly measurable. Using these parameters, the performance of the membrane can be examined based on determination of  $CO_2/CH_4$  selectivity and permeance. The experiments were completed by evaluating the performance of membrane in two different conditions: the first is the feed gas stream without any hydrocarbon, namely **Dry Condition** and the second is the feed gas stream with heavy hydrocarbon (pentane) as **Wet Condition**.

The investigated operating parameters for the performance of membranes system are as follow:

Feed Pressure	= 10, 20, 40 and 50 bar
Operating Temperature	$= 30, 40 \text{ and } 50^{\circ} \text{C}$
Concentration of CO <sub>2</sub> in feed gas	= 25, 40, 55 and 70 % of CO <sub>2</sub>

Prior to the experiments, the flat sheet polyimide membrane is cut into a round shape by using a sharp razor blade and put into a membrane test cell holder. For the permeation tests, the manipulated variables of the experiments are feed pressure, temperature and carbon dioxide concentration in natural gas feed stream. **Pentane** is used to simulate the presence of heavy hydrocarbon in natural gas stream. The total feed stream flow rate is 50 SLPM (Standard Liter per Minute). The first set of experiment was started with 25%  $CO_2/75\%$  CH<sub>4</sub> feed stream without any hydrocarbon at 30 °C and 10 bar. The same experiments were repeated in dry condition vary according to the specified feed pressure, temperature and CO<sub>2</sub> concentration in feed stream. A total of 48 set of experiments with different combination of feed pressure, temperature and CO<sub>2</sub> concentration in feed stream were repeated to evaluate the performance of polyimide membrane in dry condition. Similarly, for wet condition, the experiments were repeated with different combination of feed pressure and CO<sub>2</sub> concentration in feed stream is the presence of heavy hydrocarbon.

In order to study the effect of heavy hydrocarbon in the feed stream, the selectivity and permeance of the membrane from the same module are compared. Subsequently, the effect of pentane on  $CO_2$  permeance,  $CH_4$  permeance and  $CO_2/CH_4$  selectivity were studied. Testing with the same module minimizes the processing variability that could occur between modules and to avoid any hysteresis effect on the membrane performance.

## 3.2.1 Material

The polyimide membrane used in this experimental works is Matrimid® 5218, a commercially available polyimide made from the monomers 3,3',4,4'-benzophenone tetracarboxylic dianhydride and diaminophenylindane (Vu, et al., 2003a). The chemical structure and physical properties of the Matrimid® 5218 membrane was shown in **Table 3.1**. Matrimid® 5218 membrane possess high glass transition temperatures,  $T_g = 302^{\circ}C$  and density 1.24 g/cm<sup>3</sup>. The Matrimid® 5218 membrane used in this study was purchased from Alpha Membrane Hi-Tech Pte. Ltd., Singapore.

Table 3.1: Chemical structure and physical properties of Matrimid® 5218.

Polymer	Chemical Structure	Density (g/cm <sup>3</sup> )	T <sub>g</sub> (°C)
Matrimid® 5218	-n-t-t-t-t-t-t-t-t-t-t-t-t-t-t-t-t-t-t-	1.24	302

Adapted from White et al., (1995).

The properties of the polyimide membrane used in the experiments are summarized in the table below:

Table 3.2: Polyimide Membrane Specification

Membrane Type	Polyimide Flat Sheet Membrane
Membrane Configuration	Asymmetric Membrane
Membrane Diameter	4.35 cm
Membrane Area	14.86 m <sup>2</sup>
Membrane Thickness	200 micrometer
Condition	Dry State
Supplier	Alpha Membrane Hi-Tech Pte. Ltd., Singapore

### 3.2.2 Gas Permeation Experiments

Experimental laboratory works were conducted to evaluate the performance of the membrane in separating carbon dioxide from natural gas. The equipment set used for the experiment is **Carbon Dioxide Separation Membrane Unit (CO2SMU)**. Polyimide membrane in flat module is inserted into a membrane test cell where natural gas and gas carbon dioxide will pass through it for the permeation tests. Carbon Dioxide Separation Membrane Unit (CO2SMU) consists of different unit operations as follows:

- i. Gas Feeding System (Automatic mass flow controller)
- ii. Heating System (Oven)
- iii. Compression System (Compressor)
- iv. Back Pressure Regulator, Pressure Gauges and Transmitters System
- v. Saturation System (Saturation Vessel)
- vi. Separation System (Membrane Test Cell, Mixed Gas Flow Meter, Infrared (IR) Gas Analyzer)
- vii. Post Treatment System (Toxicap Fume Hood)

Figure 3.5: Carbon Dioxide Separation Membrane Unit (CO2SMU) at Block N, UTP

### 3.2.3 Experimental Setup of Carbon Dioxide Separation Membrane Unit

The experimental set-up for the full-scale module of Carbon Dioxide Separation Membrane Unit (CO2SMU) is illustrated in **Figure 3.6**.

Figure 3.6: Flow Diagram of Experimental Setup for Carbon Dioxide Separation Membrane Unit (CO2SMU)

CO2SMU is equipped with a heating system or an oven (represented by the red boxes in Figure 3.6) where all the major equipment and process piping are stored in the oven. The gas feeding line and the membrane module were leak tested using nitrogen prior to the gas separation experiments. The gas feeding line consists of Natural Gas (NG), Methane (CH<sub>4</sub>), Carbon Dioxide (CO<sub>2</sub>), Nitrogen (N<sub>2</sub>), and an additional point for other gases. Gas feeding system in CO2SMU consists of **automatic mass flow controller** serves as mass air flow sensor, controller and flow meter. The digital mass flow controller can be used to adjust and measure the flow rate of the gases before sending to feed vessel. The feed gases from gas tanks were admitted to **feed vessel** and **static mixer** to mix multiple gas streams homogeneously before entering gas compressor or saturation vessel. The feed pressure was automatically set with a pressure controller (use either Equilibar or Bronkhorst) in this experiment. For experiments in dry condition (without heavy hydrocarbon), the feed gases bypass the saturation vessel. CO2SMU is a one-stage flow scheme where a feed gas is separated into a permeate stream rich in  $CO_2$  and a retentate stream rich in methane. Polyimide membrane is placed in a membrane test cell which contains milipore pressure filter holder (XX45 047 00). It is equipped with a pressure relief valve. The feed and residue flow rates were measured with mixed gas flow meter (Coriolis Digital Flow Controller) and the permeate flow rate was measured with a Rotameter. The membrane module was flushed with pure nitrogen after each experiment to avoid the accumulation of any remaining hydrocarbon on membrane test cell.

For temperature control, the entire set-up of COSMU (except compressor, gas analyzer, gas feeding and gas storage system) are stored in the oven. The temperature inside the oven can be controlled from ambient temperature to 100 °C. The temperatures and pressures of all the gas streams (namely, feed, permeate and retentate) were monitored by thermocouples and pressure transducers, respectively. The measured gas flow rate, temperature and pressure were all logged onto a computer using data logger. All experimental data were continuously monitored. The gas composition was analyzed by an **Infra-red (IR) Gas Analyzer** that was equipped with a thermal conductivity detector. At least three samples were collected and analyzed to determine the gas composition and the concentrations were measured in terms of mol% or vol%. The CO2SMU is equipped with a **Toxicap Fume Hood** as a post treatment system to filter the impurities prior to vent the gases to atmosphere.

#### 3.2.4 Experiment Procedures

The start-up procedures of the experiment are as the following:

- 1. The main breaker/isolator (MEM/EATON) in the main panel board is switched on.
- 2. The MCB breakers in control panel board are switched on.

 i) Control Panel 1: On switches for Compressor 1 and Compressor 2. All MCB breakers are switched on except MCB 3.

- ii) Control Panel 2: All MCB breakers are switched on except MCB 1.
- 3. Analyzer switch, Hot Box switch and computer are switched on.
- 4. The valves of the three gas tubes for Natural gas, carbon dioxide and nitrogen tanks are opened.
- 5. The heater regulator for carbon dioxide is switched on.
- 6. The value of the mass flow controller (SIERRA digital mass flow controller) is set based on the desired value in standard liter per minute (SLPM).
- 7. The valves for gas inlet of  $CO_2$  and  $CH_4$  and the outlet valve of mass flow controller are opened.
- 8. The heater regulator for  $CH_4$  and  $CO_2$  are set to 7 bars and 100psi, respectively.
- 9. The temperature of the oven is set from the control panel.
- 10. Polyimide membrane is prepared with diameter of 4.5 cm and put in the membrane test cell.
- 11. For experiments in dry conditions (without heavy hydrocarbon), the system will bypass the saturation vessel. Saturation vessel is only used for experiments in wet conditions (with heavy hydrocarbon) to saturate mixed gases with heavy hydrocarbon (pentane as a basis).
- 12. The valve of equilibar is opened, the valve of Bronkhorst and by-pass valve of Flow Meter 2, FM 02 are closed.
- 13. The valve of membrane test cell is opened to allow the mixed gases pass through the membrane. The total feed flow rate of mixed gases is set at 50 SLPM.

- 14. The mixture of methane and carbon dioxide gases pass through the membrane test cell. The feed and residue flow rates were measured with mixed gas flow meter (Coriolis Digital Flow Controller) and the permeate flow rate was measured with a Rotameter.
- 15. The temperatures and pressures of feed, permeate and retentate streams were monitored by thermocouples and pressure transducers, respectively and the raw data were all logged onto a computer using data logger.
- 16. The gas composition was analyzed by an Infra-red (IR) Gas Analyzer that was equipped with a thermal conductivity detector.
- 17. The same experiments are repeated for pressure of 10 bar, 20 bar, 40 bar and 50 bar while the temperature maintain at 30 °C with 25 % concentration of carbon dioxide in feed gas.
- 18. The same experiments are repeated for the following operating conditions:
  - a. Feed Pressure = 10, 20, 40 and 50 bar
  - b. Operating Temperature  $= 30, 40 \text{ and } 50 \text{ }^{\circ}\text{C}$
  - c. Concentration of carbon dioxide in feed gas = 25, 40, 55 and 70 %
- 19. In dry condition, 48 set of experiments with different combination of feed pressure, temperature and CO<sub>2</sub> concentration in feed stream were completed to evaluate the performance of polyimide membrane.
- 20. Procedures 1 to 18 are repeated to evaluate the performance of polyimide membrane with the presence of hydrocarbon (in wet condition). Liquid Pentane will be filled into saturation vessel to allow the mixed gases in feed stream saturated with heavy hydrocarbon before sending to membrane test cell.

**Figure 3.7:** Liquid Pentane for experiments in Wet conditions

# **CHAPTER 4**

# **RESULTS AND DISCUSSION**

# 4.1 DATA GATHERING

In this report, polyimide flat sheet membrane was used in the experiments to study the effect of pentane on the membrane performance. For the gas permeation tests, the manipulated variables of the experiments are feed pressure, temperature and carbon dioxide concentration in natural gas feed stream. Since heavy hydrocarbons and aromatics compound can bring significant effect to the performance of polyimide membrane, pentane is used to simulate the presence of heavy hydrocarbon in the working environment in laboratory. A flat sheet polyimide membrane with an area of 14.86 cm<sup>2</sup> was tested with both mixed gas measurements in both Dry (without pentane) and Wet (with pentane) conditions, and the CO<sub>2</sub>/CH<sub>4</sub> permeance and selectivity of the membrane are calculated to evaluate the performance of the membrane. The permeance is expressed as a thickness normalized permeability and is given in gas permeation units, GPU (1 GPU =  $10^{-6}$  cm<sup>3</sup> (STP) cm<sup>-2</sup> s<sup>-1</sup> cm Hg<sup>-1</sup>). The selectivity of the mixed gas was calculated as the ratio of the respective gas permeance obtained in the experiments.

In order to calculate the permeance of  $CO_2$  and  $CH_4$ , the membrane system is treated as a complete-mixing model for gas separation. According to Weller and Steiner, the permeate flow rate is a small fraction of the entering feed rate when a membrane system is operated at a low recovery, and thus, there is a minimal change in composition. With the use of complete-mixing model, the permeance of  $CO_2$  and  $CH_4$  and selectivity can be calculated.

# Complete-Mixing Model for gas separation by polyimide membranes

A detailed process flow diagram is shown for complete mixing for gas separation by polyimide membrane in **Figure 4.1** (Geankoplis, 2003). The section below will explain the steps of calculations and theories involved in the project in order to channel the results obtained to graphical form.

Figure 4.1: Process flow for complete mixing case. Adapted from Geankoplis (2003). Using the feed and non-permeate flow rate as L and composition x (in mole fraction) and the permeate flow rate as V and composition y (in mole fraction), the overall material balance is as follows:

$$L_f = L_o + V_p$$

where  $L_f$  is total feed flow rate, cm<sup>3</sup> (STP)/s;  $L_o$  is outlet reject flow rate, cm<sup>3</sup> (STP)/s;  $V_p$  is outlet permeate flow rate, cm<sup>3</sup> (STP)/s

The stage cut or fraction of feed permeated,

$$\theta = \frac{V_p}{L_f}$$

The rate of diffusion or permeation of species A (in a binary of A and B) is given below:

$$\frac{V_A}{A_m} = \frac{V_p y_p}{A_m} = \left(\frac{P'_A}{t}\right) \left(p_h x_o - p_l y_p\right)$$

Where  $P'_A$  is permeability of A in the membrane, cm<sup>3</sup> (STP)  $\cdot$  cm/(s  $\cdot$  cm<sup>2</sup>  $\cdot$  cm Hg);  $V_A$  is flow rate of A in permeate, cm<sup>3</sup> (STP)/s;  $A_m$  is membrane area, cm<sup>2</sup>; t is membrane thickness, cm;  $p_h$  is total pressure in the high-pressure (feed) side, cm Hg;  $p_l$  is the total pressure in the low pressure or permeate side, cm Hg;  $x_o$  is mole fraction of A in reject side;  $x_f$  is mole fraction of A in feed; and  $y_p$  is mole fraction of A in permeate.

A similar equation can be written for component B.

$$\frac{V_B}{A_m} = \frac{V_p(1-y_p)}{A_m} = \left(\frac{P'_B}{t}\right) \left[ p_h(1-x_o) - p_l(1-y_p) \right]$$

where  $P'_B$  is permeability of B in the membrane, cm<sup>3</sup> (STP)  $\cdot$  cm/(s  $\cdot$  cm<sup>2</sup>  $\cdot$  cm Hg).

(Note:  $p_h x_o$  is the partial pressure of A in the reject gas phase and  $p_l y_p$  is the partial pressure in the permeate side. Component A = CO<sub>2</sub> and Component B = CH<sub>4</sub>)

The ideal selectivity,  $\alpha^*$ 

$$\alpha^* = \frac{P_A'}{P_B'}$$

where  $P'_A$  is permeability of A in the membrane, cm<sup>3</sup> (STP)  $\cdot$  cm/(s  $\cdot$  cm<sup>2</sup>  $\cdot$  cm Hg) and  $P'_B$  is permeability of B in the membrane, cm<sup>3</sup> (STP)  $\cdot$  cm/(s  $\cdot$  cm<sup>2</sup>  $\cdot$  cm Hg).

The gas-mixed (real) selectivity (separation factor),  $\alpha_{A/B}$ 

$$\alpha_{A/B} = \left(\frac{y_A}{y_B}\right) \cdot \left(\frac{x_B}{x_A}\right)$$

where  $x_A$  is mole fraction of A in feed,  $y_A$  is mole fraction of A in permeate,

 $x_B$  is mole fraction of B in feed,  $y_B$  is mole fraction of B in permeate.

All the results of experiments are summarized in table form (for both dry and wet conditions) as shown in appendices.

### 4.2 DATA ANALYSIS

### 4.2.1 Effect of Operating Pressure

Feed pressure contributes to significant effects of the membrane performance. It serves as one of the main driving forces with feed concentration and temperature for membrane separation (Hwang et al., 2011). By using a compressor at the feed side, the pressure difference across the polyimide membrane was controlled in the experiments. The dry condition is a situation where there is no existence of pentane in the feed gas stream whereas the wet condition is the feed gas stream with pentane to simulate heavy hydrocarbon as aforementioned. To study the effects of pentane on operating pressure on the performance of membrane,  $CO_2$  permeance and CO2/CH4 selectivity are plotted versus the feed pressure in both dry and wet condition as shown in **Figure 4.2**.

The effects of the operating pressures with 40% of CO<sub>2</sub> concentration in mixed gas feed stream at 50 °C is showed in Figure 4.2. The feed pressure was varied in 10 bar steps from 10 to 50 bar<sub>a</sub> with 40% of CO<sub>2</sub> concentration in mixed gas feed stream at 50 °C. It was speculated that the presence of pentane in the feed might influence the

membrane performance. Experimental results were shown in **Figure 4.2** with the plot of  $CO_2$  permeance and  $CO_2/CH_4$  selectivity as a function of operating feed pressure. Higher operating pressures at the feed side demonstrated decreased permeance of  $CO_2$  in both dry and wet conditions. It is obvious that the  $CO_2$  permeance decreases with the increased of feed pressure whereas the  $CO_2/CH_4$  selectivity increased with higher operating pressures in both dry and wet conditions. An increased operating pressure resulted in low permeation flux but high  $CO_2/CH_4$  selectivity.

Similarly, the CH<sub>4</sub> permeance displayed an inverse relationship with the increased of operating pressures as shown in **Figure 4.3**. The higher the operating feed pressure, the lower the CH<sub>4</sub> permeance on the membrane performance. The  $CO_2/CH_4$  selectivity in Wet Condition is higher than  $CO_2/CH_4$  selectivity in Dry Condition.

**Figure 4.3:** CH<sub>4</sub> permeance as a function of operating feed pressure. Temperature: 50 °C and Feed Composition: 40% of CO<sub>2</sub> concentration.

Initially, the experimental results were suspected as experimental inaccuracies. Therefore, several set of experiments were conducted to verify the consistency and reproducibility of the experimental results. The experimental results are further corroborated in **Figure 4.4** and **4.5** where the permeance of  $CO_2$ ,  $CH_4$  and  $CO_2/CH_4$  selectivity are plotted as a function of operating pressure.

In Figure 4.4 and 4.5, the operating temperature of the experiment is 30 °C with 55% of  $CO_2$  concentration in mixed gas feed stream. The results showed that both  $CO_2$  and  $CH_4$  permeance varied instantaneously with the change in feed pressure.

**Figure 4.4:** CO<sub>2</sub> Permeance and CO<sub>2</sub>/CH<sub>4</sub> Selectivity as a function of operating feed pressure. Temperature: 30 °C, Feed Composition: 55% of CO<sub>2</sub> concentration.

**Figure 4.5:** CH<sub>4</sub> Permeance as a function of operating feed pressure. Temperature: 30 °C, Feed Composition: 55% of CO<sub>2</sub> concentration.

Since the trend of graphs is similar in the previous case, it is confirmed that the results on the effects of operating pressures are valid.

A major problem that always encountered for gas separation in glassy polymer, especially for separation of  $CO_2/CH_4$  is plasticization (Liu, Wang, & Chung, 2001). Plasticization pressure of polyimides is normally above 10 bar (Bos, Pünt, Wessling, & Strathmann, 1999). From the gas permeance versus pressure plot, the minimum pressure noticed is called the plasticization pressure. At **Figure 4.2** and **4.4**, the minimum permeance of  $CO_2$  was observed at the pressure of 50 bar for the  $CO_2$  permeance versus pressure plot. This indicates that the polyimide membrane was undergoing the plasticization phenomenon at that particular pressure. For glassy polymer, the  $CO_2$  permeance decreases with increasing feed pressure can be explained by the dual sorption model. An increase of operating pressure will diminish the rate of the permeation flux (Shi, Kong, Yu, Wang, & Yang, 2006). Plasticization is highly undesired since it will cause a drastic decrease in selectivity when mixed gas experiments are performed. To overcome this problem, cross-linking modification can be applied when it can enhance the transport properties of polymeric membrane and reduce the plasticization effect.

The ratio of the permeate flux to the feed flux is known as Stage cut. As shown in **Figure 4.6**, the increasing feed pressure decreased the stage cut. There is a slight increase of stage cut with the presence of pentane, indicating a plasticization effect, where more permeate flow through the membrane at Wet condition compare to Dry condition.

Figure 4.6: Stage Cut as a function of feed pressure. Temperature: 30 °C, Feed Composition: 55% of CO<sub>2</sub> concentration.

An increase in feed pressure resulted in  $CO_2$  permeance decreases but  $CO_2/CH_4$  selectivity increases in polyimide membrane. A greater driving force across the membrane can be created with the increase in operating pressure and thus, the membrane selectivity increases and less membrane area requirement for the system.

Generally, the designers of the membrane system will attempt to utilize the maximum operating pressure possible to obtain a cheaper, smaller and effective system as the membrane area requirement is highly affected by the feed pressure (Dortmundt & Doshi, 1999). Also, the designers have to take into consideration of the cost and weight of equipment at a higher pressure rating and the maximum pressure limit for the membrane elements to withstand in equipment detailed design.

#### 4.2.2 Effect of Operating Temperature

Operating temperature plays an important role on the performance of polyimide membrane. The permeability of membrane increases with an increase in feed temperature but membrane selectivity decreases. An increase in feed temperature also results in decrease of membrane area requirement and causes the increases of hydrocarbon losses (Dortmundt & Doshi, 1999).

The effects of pentane on operating temperature can be observed from the plot of  $CO_2$  permeance and  $CO_2/CH_4$  selectivity versus temperature as shown in Figure 4.7. According to Hogsett & Mazur (1983), the permeability of most polymers increases with the increased of operating temperature but contributes to a slight decreases in selectivity. The operating temperature is chosen to be above the dew point of the residue gas in the range of 30 to 50 °C. Based on Figure 4.7, it is shown that higher temperature produced higher  $CO_2$  permeance whereas  $CO_2/CH_4$  selectivity decreased with the increase of operating temperature in both dry and wet condition. Figure 4.7 also depicted the  $CO_2$  permeance in dry condition is higher than wet condition at 30 °C but  $CO_2$  permeance in dry condition is lower than  $CO_2$  permeance in wet condition at 40 and 50 °C.

**Figure 4.7:** The effects of operating temperature on the CO<sub>2</sub> permeance and CO<sub>2</sub>/CH<sub>4</sub> selectivity. Pressure: 50 bar and Feed composition: 55% CO<sub>2</sub> concentration.

The CO<sub>2</sub>/CH<sub>4</sub> selectivity is about 0.961 and 0.948 for polyimide membrane at 50  $^{\circ}$ C and 50 bar in dry and wet condition, respectively as shown in **Figure 4.7**. The CO<sub>2</sub>/CH<sub>4</sub> selectivity for both dry and wet conditions is quite similar and close to unity, this indicates there is less separation of CO<sub>2</sub> from the mixed gas experiments. At high CO<sub>2</sub> partial pressures, there is considerable CO<sub>2</sub> absorbed in the membrane. The plasticization effect of CO<sub>2</sub> increases the effective diffusion coefficients for all gases and makes the selectivity less than that based on pure-gas data (Hogsett & Mazur, 1983).

Similarly, CH<sub>4</sub> permeance is higher at Wet condition compare to Dry condition versus operating temperature plot as shown in Figure 4.8.

**Figure 4.8:** The effects of operating temperature on the CH<sub>4</sub> permeance. Pressure: 50 bar and Feed composition: 55% CO<sub>2</sub> concentration.

The decreasing selectivity of  $CO_2/CH_4$  can be explained in terms of a difference in permeation activation energy between gases. Equation of activation energy, Q = Aexp [-E/RT], contributes to the change in permeability where the activation energies, E that range from 1 to 5 kcal/mol (Hwang, et al., 2011). The  $CO_2$  and  $CH_4$  permeance through the membrane layer increased with an increase in the operating temperature due to the increase in activation energy of permeate gases but the selectivity of gas pairs decreased. In industrial applications, natural gas stream is often heated to prevent condensation of heavy hydrocarbons in feed stream. Generally, the gas permeability of membranes can be improved by high temperature. However, high operating temperature can often degrade the membrane performance at the same time.

The stage cut is determined as the ratio of the permeate flow rate (kg/h) to the feed flow rate (kg/h). The increasing operating temperature increased the stage cut as shown in **Figure 4.9**.

Figure 4.9: Stage Cut as a function of operating temperature. Pressure: 50 bar, Feed Composition: 55% of CO<sub>2</sub> concentration.

Based on Figure 4.9, it is indicated that more permeate flow through the membrane system as the temperature increases. At 30 °C, we noticed that the stage cut for both Dry and Wet Conditions are similar, this shows that the separation performance has no vast different at room temperature (about 30 °C) compare to high temperature (40 to 50 °C). The graphs also showed that the stage cut is higher in Wet Condition with the influence of pentane than the stage cut in Dry Condition as a function of operating temperature. The effect of pentane caused more permeates flow through the membrane and thus contributed to higher stage cut value.

High gas productivity can be achieved at higher operating temperatures; however, the gas purity will be affected due to the decrease of selectivity at high temperature. From **Figure 4.10**, the selectivity at dry condition is higher than selectivity at wet condition with an increase in operating temperature. Without the presence of pentane, higher gas productivity was obtained in the mixed gas experiment. Generally, a minimum selectivity of 4 is needed for a good membrane separation. Low  $CO_2/CH_4$  selectivity obtained in this project can be related to the defect of polyimide membrane or the presence of pentane. Further studies have to be conducted to investigate on these matters.

**Figure 4.10:** CO<sub>2</sub>/CH<sub>4</sub> selectivity as a function of Temperature (T). Pressure: 50 bar and Feed composition: 55% CO<sub>2</sub> concentration.

For most polymeric membrane, the permeability of membrane increases with temperature due to the increase of diffusivity more than offsets any decrease in solubility. Since the membrane selectivity is inversely proportional to the operating temperature, an increase in temperature often decreases the selectivity of membrane. Therefore, the operating temperature is usually determined based on the trade-off between high temperature and high selectivity. Also, the existence of pentane decreased the membrane selectivity but increased permeability at high operating temperature in the mixed gas experiments.

### 4.2.3 Effect of Feed Composition

The effects of pentane on feed composition can be observed from the plot of  $CO_2$  permeance and  $CH_4$  permeance versus  $CO_2$  concentration in feed stream as shown in Figure 4.11 and 4.12.

Figure 4.11: CO<sub>2</sub> Permeance as a function of feed composition. Pressure: 50 bar and Temperature: 30 °C.

**Figure 4.12:** CH<sub>4</sub> Permeance as a function of feed composition. Pressure: 50 bar and Temperature: 30 °C.

The CO<sub>2</sub> mole fraction has a significant impact on the bulk contribution of CO<sub>2</sub> and CH<sub>4</sub>. The CO<sub>2</sub> and CH<sub>4</sub> permeance decreases with an increase in CO<sub>2</sub> concentration in feed composition due to the plasticization and compaction effect. Generally, an increase in CO<sub>2</sub> concentration in feed stream increases the losses of hydrocarbon and membrane area. This is because the more CO<sub>2</sub> permeate; the more hydrocarbons permeate through the membrane (Dortmundt & Doshi, 1999). Based on **Figure 4.11**, it is shown that the CO<sub>2</sub> permeance decrease with an increase in CO<sub>2</sub> concentration in the feed stream. Similarly, the CH<sub>4</sub> permeance decreased with an increase in CO<sub>2</sub> concentration in CO<sub>2</sub> concentration as shown in **Figure 4.12**.

This phenomenon can be explained by a coupling effect which is often due to the presence of other gas, such as pentane or methane in the mixed gas stream. The coupling effect on permeation is strongly related to deviations in the solubility coefficient, while the diffusivity coefficient is not affected by the presence of other gas (Hwang, et al., 2011). As CO<sub>2</sub> concentration in the feed increases, the solubility coefficient increases while the diffusivity coefficient is remained constant and thus, resulting in an increase in  $CO_2$  permeance and concentration in permeate.

Asymmetric polyimide membranes with high  $CO_2/CH_4$  selectivity are highly sensitive to the presence of heavy hydrocarbons in the feed. As shown in **Figure 4.13**, The  $CO_2/CH_4$  selectivity decreases with the increase in  $CO_2$  concentration in the feed stream.

Figure 4.13: CO<sub>2</sub>/CH<sub>4</sub> selectivity as a function of feed composition. Pressure: 50 bar and Temperature: 30 °C.

Based on Figure 4.13, it can be observed that the CO<sub>2</sub>/CH<sub>4</sub> selectivity at Dry condition is lower than CO<sub>2</sub>/CH<sub>4</sub> selectivity at Wet condition due to coupling effect on permeation. Upon exposure of the mixed gas to the liquid pentane in saturation vessel, the results from experiments showed that both have an immediate negative impact on membrane selectivity. It was postulated that pentane sorbed caused plasticization of the active skin layer on the polyimide membrane and thus contributing to the loss of membrane selectivity. The presence of pentane is a significant contaminant in most raw natural gas streams. The ability of pentane to permeate through this polyimide membrane indicates plasticization of the polymer membrane (White, et al., 1995). Heavy hydrocarbons and aromatics compound can bring significant effect to the performance of polyimide membrane as the presence of these components causes swelling or plasticization of glassy membranes. Thus, the selectivity of membrane will be reduced (Chenar, Savoji, Soltanieh, Matsuura, & Tabe, 2010). Also, the loss of loss of flux and membrane performance in the experiment can be related to the effect of pentane as the heavy hydrocarbon contamination even at low mass fractions (Al-Juaied & Koros, 2006).

The results presented in Figure 4.14 shows the changes of stage cut as a function of  $CO_2$  concentration in feed stream.

**Figure 4.14:** Stage Cut as a function of CO<sub>2</sub> concentration in feed. Pressure: 50 bar and Temperature: 30 °C.

The increase of  $CO_2$  concentration in feed stream decreases the stage cut of the membrane. The results indicated the stage cut is higher at Wet Condition with the influence of pentane than the stage cut at Dry Condition as a function of  $CO_2$  concentration. The effect of pentane caused plasticization of the membrane; resulting more permeates flow through the membrane and thus contributed to higher stage cut value compare to Dry condition.

The results from the feed composition effect on the membrane performance indicate that impurities and heavy hydrocarbon can bring significant effect on separation efficiency. In order to have good membrane performance,  $CO_2$  enrichment in feed gas is necessary to decrease the  $CO_2$  permeance and later increase the  $CO_2/CH_4$  selectivity. Also, the condensation of hydrocarbons in feed stream must also be avoided. Any form of liquid presence in the membrane system can increase the membrane resistance and also damage the membrane by swelling or softening.

Both permeability and selectivity are important considerations when selecting a commercial membrane. Higher permeability decreases the amount of membrane area required to treat a given amount of gas, thereby reducing the capital cost of membrane units. Higher selectivity results in higher purity product gas (Freeman, 1999). However, high  $CO_2$  permeability does not correspond to high selectivity, instead the membrane scientists have to settle for a high selective or permeable membrane or somewhere inbetween on both parameters (Dortmundt & Doshi, 1999).

Generally, polymeric membranes undergo a trade-off limitation between permeability and selectivity. As selectivity increases, the gas permeability will decrease and vice versa (Freeman, 1999). According to Dortmundt and Doshi (1999), the usual choice of membrane in industrial applications is to use a highly selective material and then make it as thin as possible to increase the permeability. However, this reduced thickness makes the membrane extremely fragile and therefore unusable.

# **CHAPTER 5**

# **CONCLUSION AND RECOMMENDATIONS**

## 5.1 CONCLUSION

In summary, the objective to study the effect on heavy hydrocarbon on polyimide membrane performance in natural gas sweetening process is successfully achieved. Parametric analyses through experimental works have been conducted to evaluate the polyimide membrane performance at different operating parameters, i.e. feed pressure, temperature and CO<sub>2</sub> concentration in feed. Higher operating pressures at the feed side demonstrated decreased permeance of CO2 and CH4 in both dry and wet conditions. An increased operating pressure resulted in low permeation flux but high CO<sub>2</sub>/CH<sub>4</sub> selectivity. The permeability of membrane increases with an increase in feed temperature but membrane selectivity decreases. The existence of pentane decreased the membrane selectivity due to plasticization effect but increased permeability at high operating temperature in the mixed gas experiments. Plasticization phenomenon happened at the pressure of 50 bars in the experiments. The CO<sub>2</sub> permeance decreases with an increase in CO<sub>2</sub> concentration in the feed stream due to coupling effect. An increase in CO<sub>2</sub> concentration in feed composition increases the losses of hydrocarbon and membrane area, and thus reduces the CO<sub>2</sub>/CH<sub>4</sub> selectivity. The presence of pentane as heavy hydrocarbon in natural gas stream contributed to the loss of membrane selectivity due to swelling, compaction or plasticization effect of glassy membrane. It can be concluded that the presence of heavy hydrocarbon reduced the separation performance of polyimide membrane.

#### 5.2 **RECOMMENDATIONS**

Experimental works in the laboratory have to be conducted based on standard procedures and must adhere to the rules and regulations to ensure personal safety. Personal Protective Equipment (PPE) has to be worn in the laboratory at all times, particularly when handling with liquid Pentane and Toluene for mixed gas experiments in Wet Conditions.

Process Optimization should be included in CO2SMU system to prevent losses of methane and other costly gases to the atmosphere. The system should be integrated with high efficiency equipment to maximize the utilities consumptions and to minimize hydrocarbon loss. Also, a vacuum pump should be installed in the CO2SMU system to ensure the membrane test cell is free from any impurities before conducting the experiment. Instead of an Infra-red (IR) Gas analyzer, a Gas Chromatography (GC) analyzer should be equipped in the membrane system since GC analyzer is more accurate and precise compare to IR Gas analyzer.

In addition, complete understanding of the observed phenomena is important for further developments and improvements of polyimide membrane. In order to fully evaluate the performance and robustness of polyimide membrane, further study of asymmetric polyimide membrane under mixed gas feeds in the presence of condensable vapor impurities is mandatory to improve the separation efficiency. The future research work should focus on the investigation of different types of impurities besides carbon dioxide and pentane, such as toluene, ethane and steady state performance of membrane. In addition, the performance of membrane should be examined under the presence of water vapor in feed streams due to the detrimental effects of condensate water vapor to polymeric membrane materials. Once the potential effects of the impurities can be identified, a more comprehensive and thorough preventive measures, particularly on the pre-treatment of process streams, pre-treatment of membrane materials, or posttreatment steps of membrane can be developed and thus contributing to the betterment of the membrane technology development in the future.
